An Actuarial Approach to Climate Change Risk: Risk of Ruin

Oliver Bettis, Institute and Faculty of Actuaries'

of Actuaries

Risk of Ruin

If climate change is primarily a risk management problem, then:

One of the most important goals of climate change policy is to *Limit the probability of very bad outcome (ruin) to acceptably small value.*

Risk of Ruin

In other words, probability “tail risk” should be a major factor in climate policy.

Martin Weitzman, Professor of Economics at Harvard, has written on this subject:

1. 2011 Fat-Tailed Uncertainty in the Economics of Catastrophic Climate Change
2. 2012 Journal of Public Economic Theory, 14 (2), 2012, pp. 221–244.
3. 2013 A Precautionary Tale of Uncertain Tail Fattening

Risk of Ruin

- 1. Capital modelling for insurance companies**
2. Capital modelling as a logical framework for climate change
3. A sketch of a climate ruin model
4. Areas for further work

Capital Protects Policyholders in case of Extreme Events

World Trade Center 9th Sept 2001

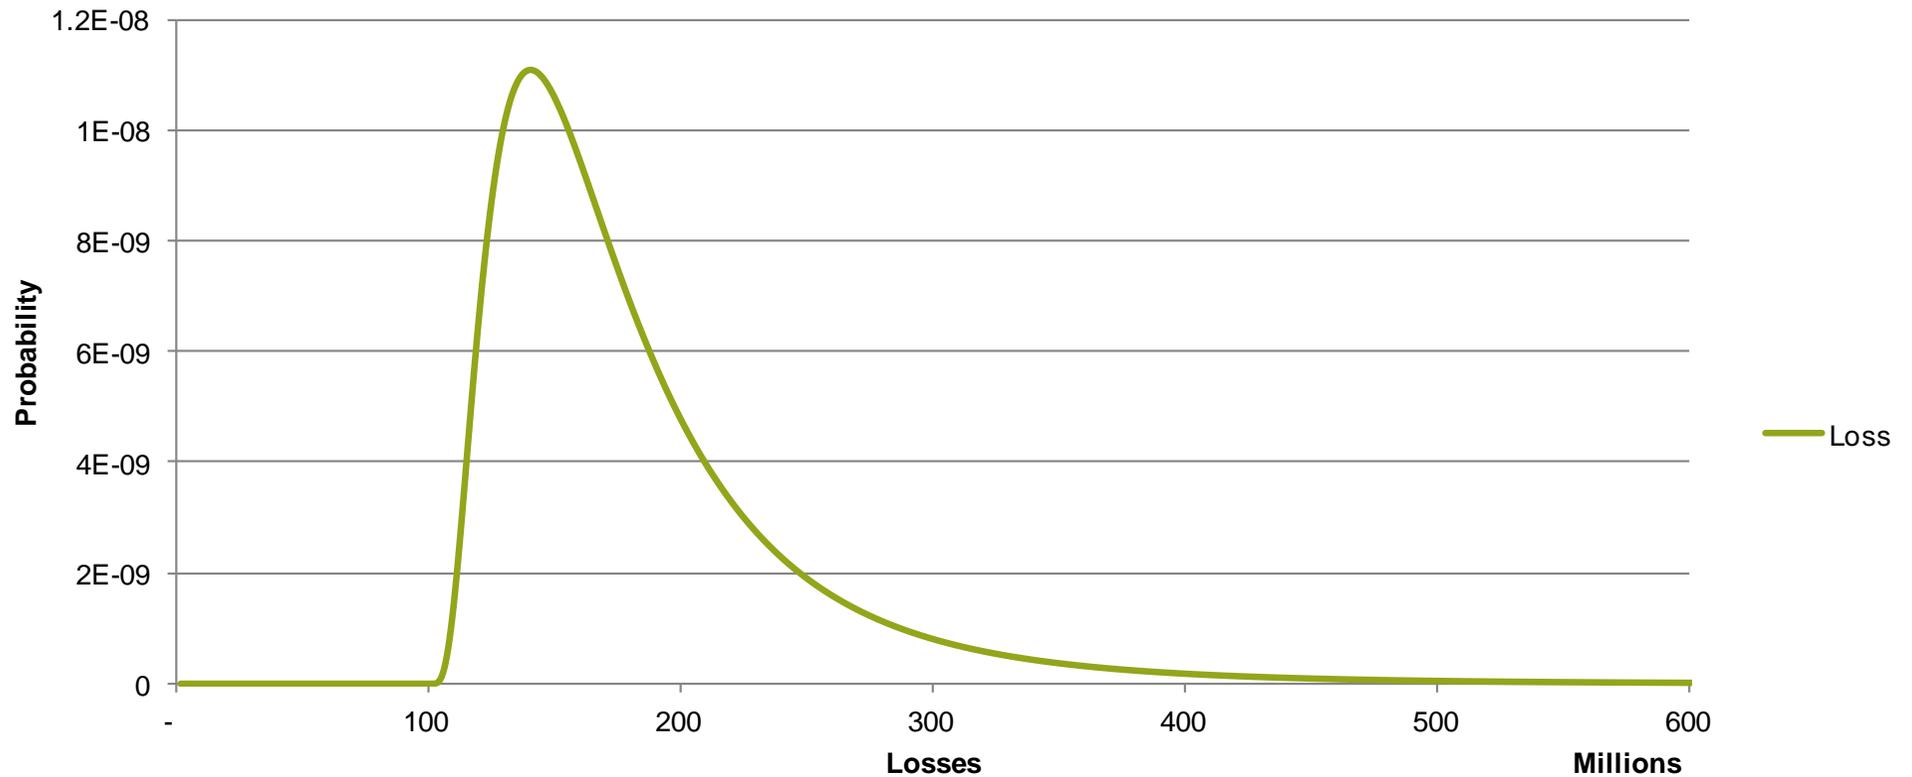

Hurricane Katrina, August 2005

Capital Modelling for Insurance Companies (under Solvency II)

- Insurance companies must hold capital so that they are protected from insolvency from any amount of claims, up to the size that would occur 1 in 200 years.
- Time horizon is one year.
- Insolvency is defined as excess of liabilities over assets i.e. the company is ruined.

Hypothetical Example – Insurance Company Claims

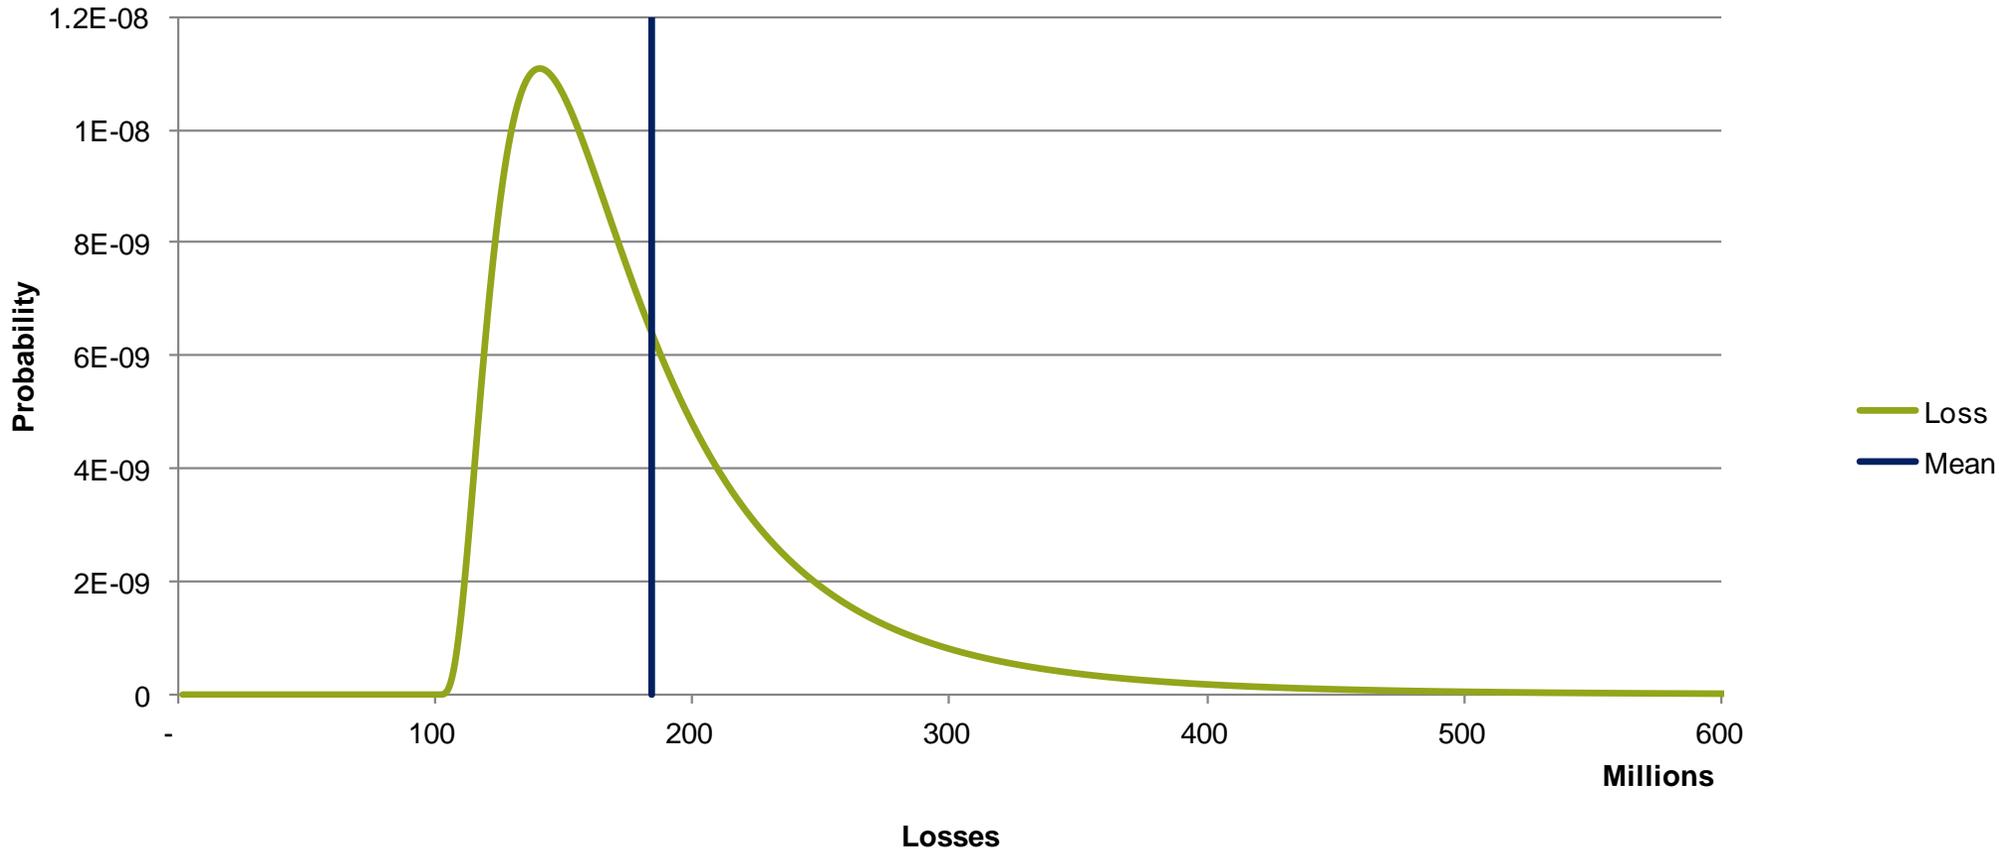

Probability Distribution for Insurance Company Losses

Hypothetical Insurance Company Claims

The mean is the “best estimate”

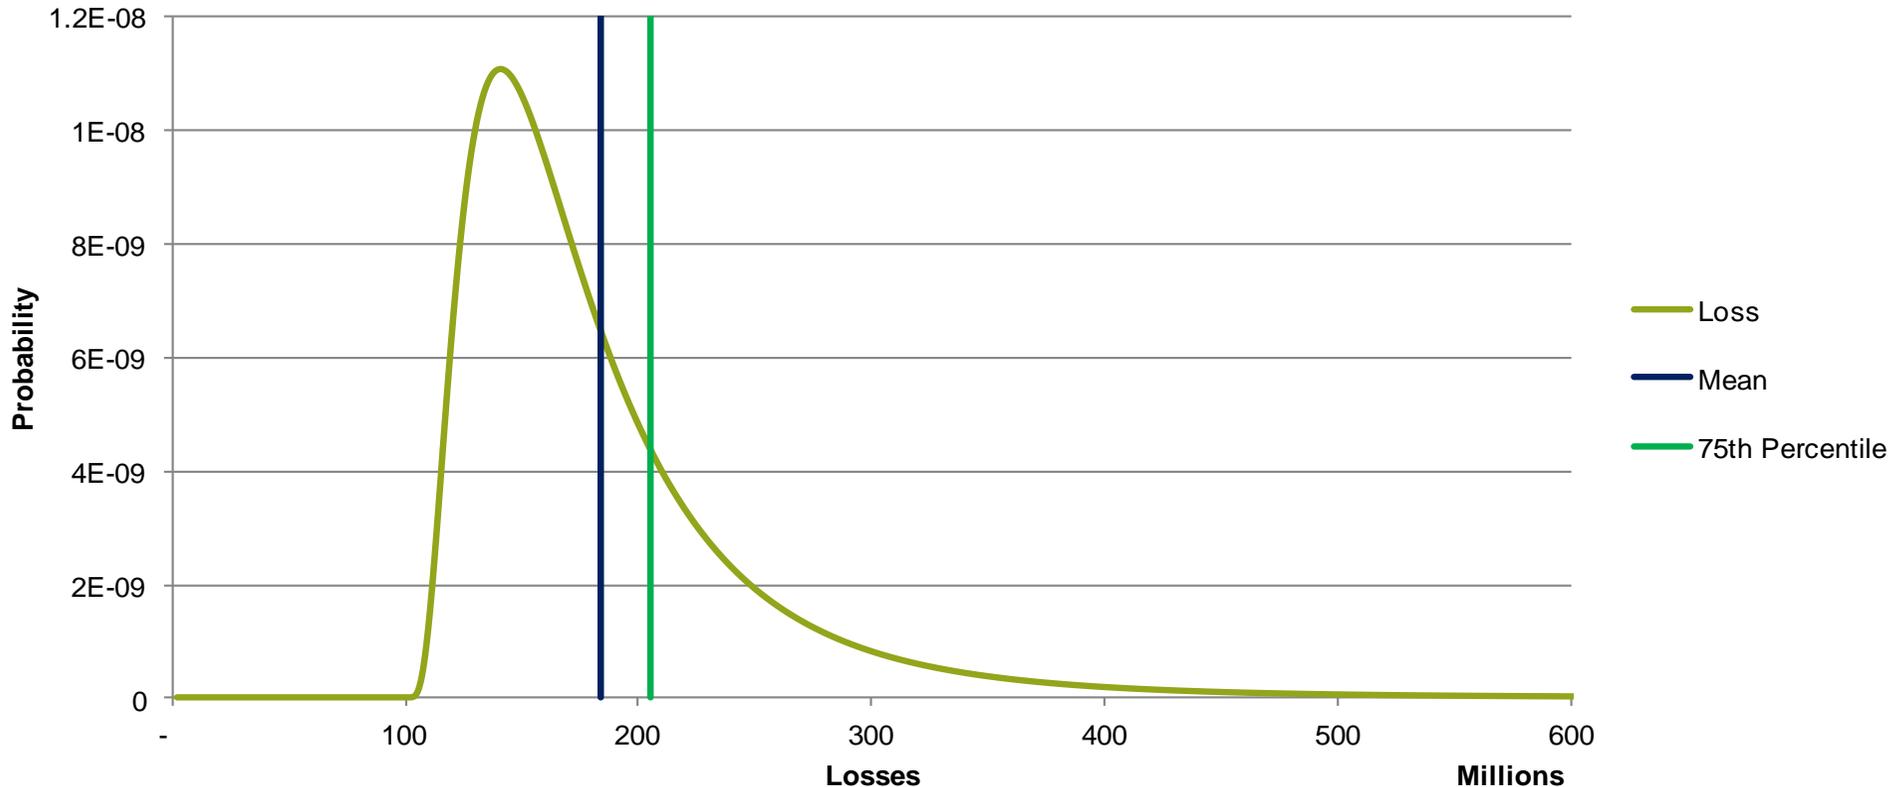

Probability Distribution for Insurance Company Losses

Hypothetical Insurance Company Claims

Claims are usually reserved conservatively*

Probability Distribution for Insurance Company Losses

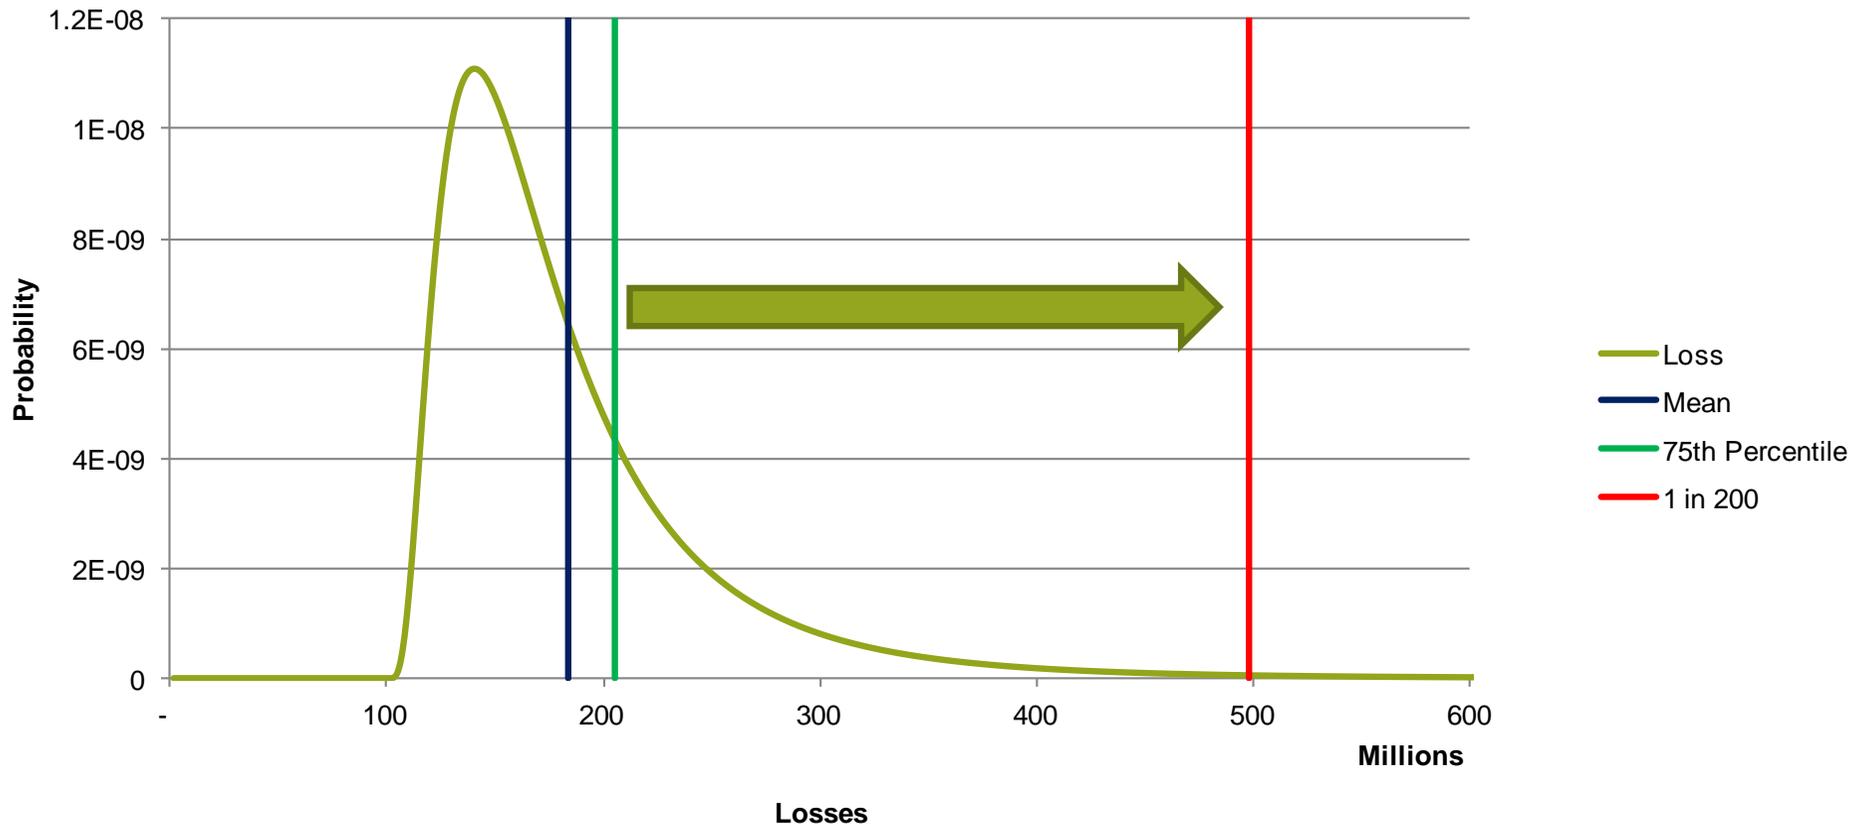

*In insurance and risk management, use of the word “conservative” denotes a high estimate.

Hypothetical Insurance Company Claims

What does the 1 in 200 level look like?

Probability Distribution for Insurance Company Losses

These values are to scale for this probability distribution.

Capital Modelling for Insurance Companies under Solvency II

- The 1 in 200 one year ruin probability is a minimum benchmark, set by the regulator.
- Insurance companies hold capital to far exceed this benchmark. (i.e. they have a lower than 0.5% one year ruin probability)
- Insurers and reinsurers are generally well-regulated and secure e.g. Munich Re founded 1880, Swiss Re founded 1863.

Risk of Ruin

1. Capital modelling for insurance companies
2. **Capital modelling as a logical framework for climate change**
3. A sketch of a climate ruin model
4. Areas for further work

Capital modelling as a logical framework

Analogy 1: The regulatory regime

Use the regulatory regime for insurance as an analogy to efforts to protect citizens from climate change:

- Capital modelling for insurance companies is part of regulatory regime to protect policyholders.
- Climate change is a danger to citizens, so the regulatory regime for climate change should be designed to protect citizens.

Capital modelling as a logical framework

Analogy 2: The regulated entity

- In insurance capital modelling, the regulated entity is the insurance company.
- In this analogy, the regulated entity is the global economy.

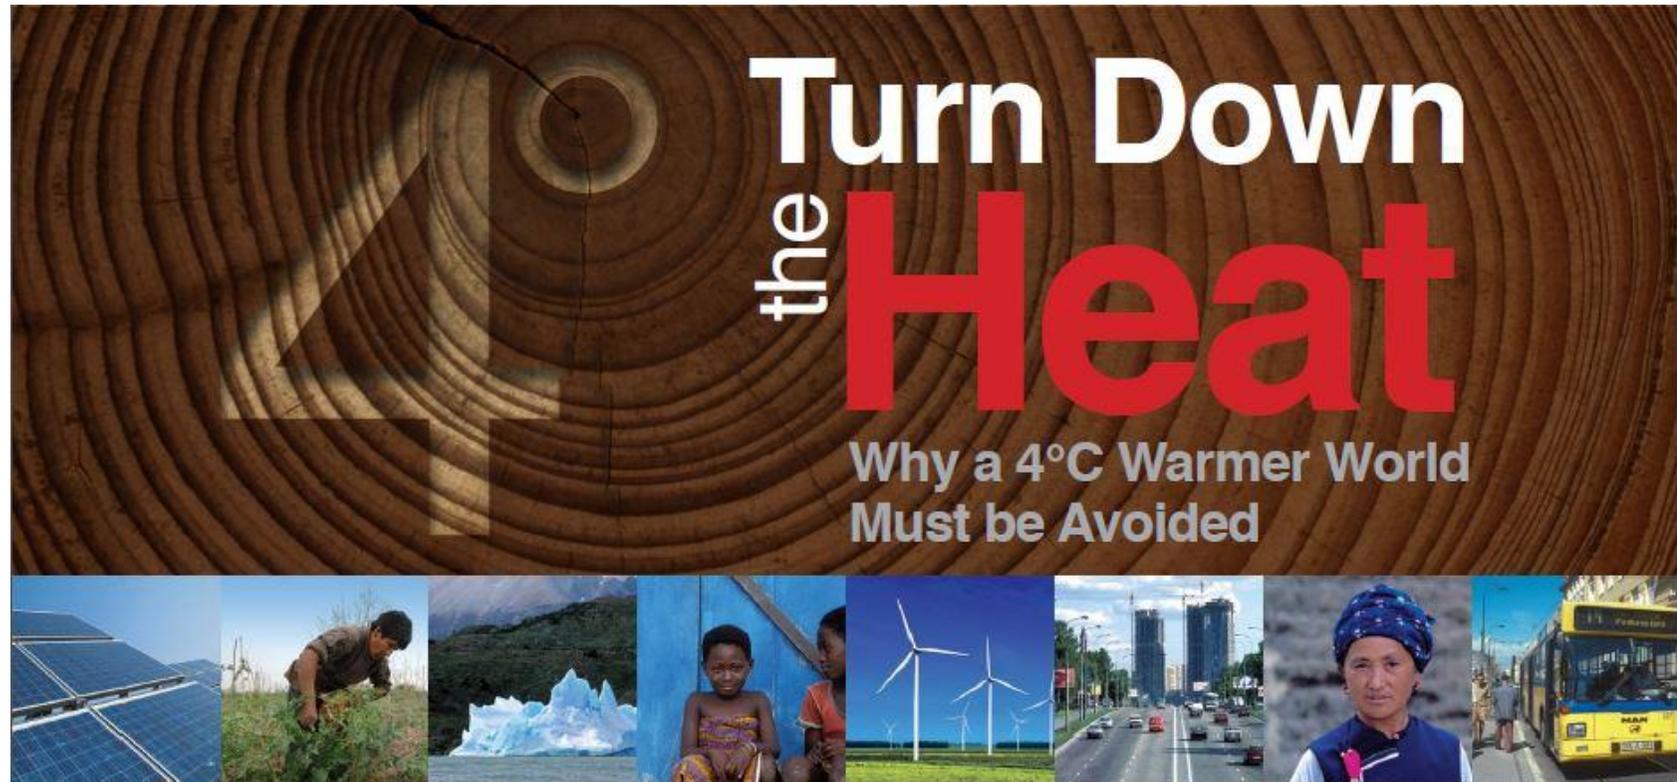

Capital modelling as a logical framework

Analogy 3: Definition of “Ruin”

- In insurance capital modelling, the ruin scenario is insolvency of the insurance company i.e. insolvency = ruin.
- Definition of climate “ruin” is a value judgement.

Selection of Climate Ruin Scenario

Choice of “ruin” scenario is a value judgement.

Why Select 4°C Temperature Rise as Ruin Scenario?

4°C warmer world would mean:

- Possible large-scale displacement of populations.
- Risk of crossing thresholds of nonlinear tipping elements in the Earth system e.g. disintegration of West Antarctic ice sheet.
- Possible nonlinear responses within particular economic sectors e.g. reduced crop yields.
- Given uncertainty about the full nature and scale of impacts, there is no certainty that adaptation to a 4°C world is possible.

Can we apply the logical framework of insurance company capital modelling to climate change?

- We have two elements for a ruin model for climate change:
 - Regulated entity; The Earth
 - Ruin scenario; 4°C global average temperature rise

Can we use this model to decide on an upper bound for an acceptable atmospheric CO₂ stabilisation target?

- Need to know:
 - Sensitivity of the climate to CO₂
 - Time horizon
 - Maximum acceptable ruin probability over this time horizon

Selection of time horizon for climate ruin model

- Climate change operates over long timescale, many delays
- Selection of time horizon is a value judgement.
- Often, future damages from climate change are discounted to present value using a discount rate.
- However, for a global issue such as climate change, should use low discount rates. See discussion paper by Nicholas Stern.
- With low discount rates, the far future matters.

What is the sensitivity of the climate to CO₂?

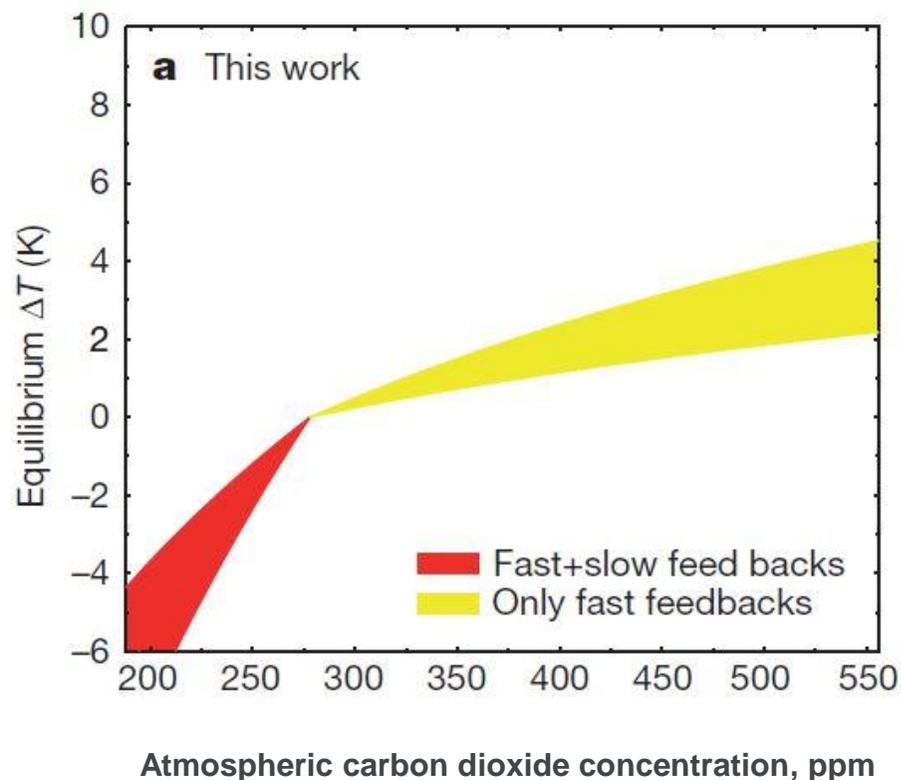

“Equilibrium Climate Sensitivity”

- The amount of warming expected at “equilibrium” of the climate system, for a given amount of greenhouse gas forcing.
- Normally calibrated to double carbon dioxide i.e. double CO₂ from the pre-industrial 280ppm to 560ppm.
- The 2013 Intergovernmental Panel on Climate Change 5th assessment report, advised that “equilibrium” climate sensitivity to doubled CO₂ was between 1.5 - 4.5 °C, with a probability of 2/3rds.

Making Sense of Paleoclimate Sensitivity Nature 2012

- But, the yellow area is the 68% confidence interval for climate sensitivity
- This gives an unacceptably high 16% tail probability
- For a risk of ruin calculation, need a much wider confidence interval.

Making Sense of Paleoclimate Sensitivity

Nature 2012

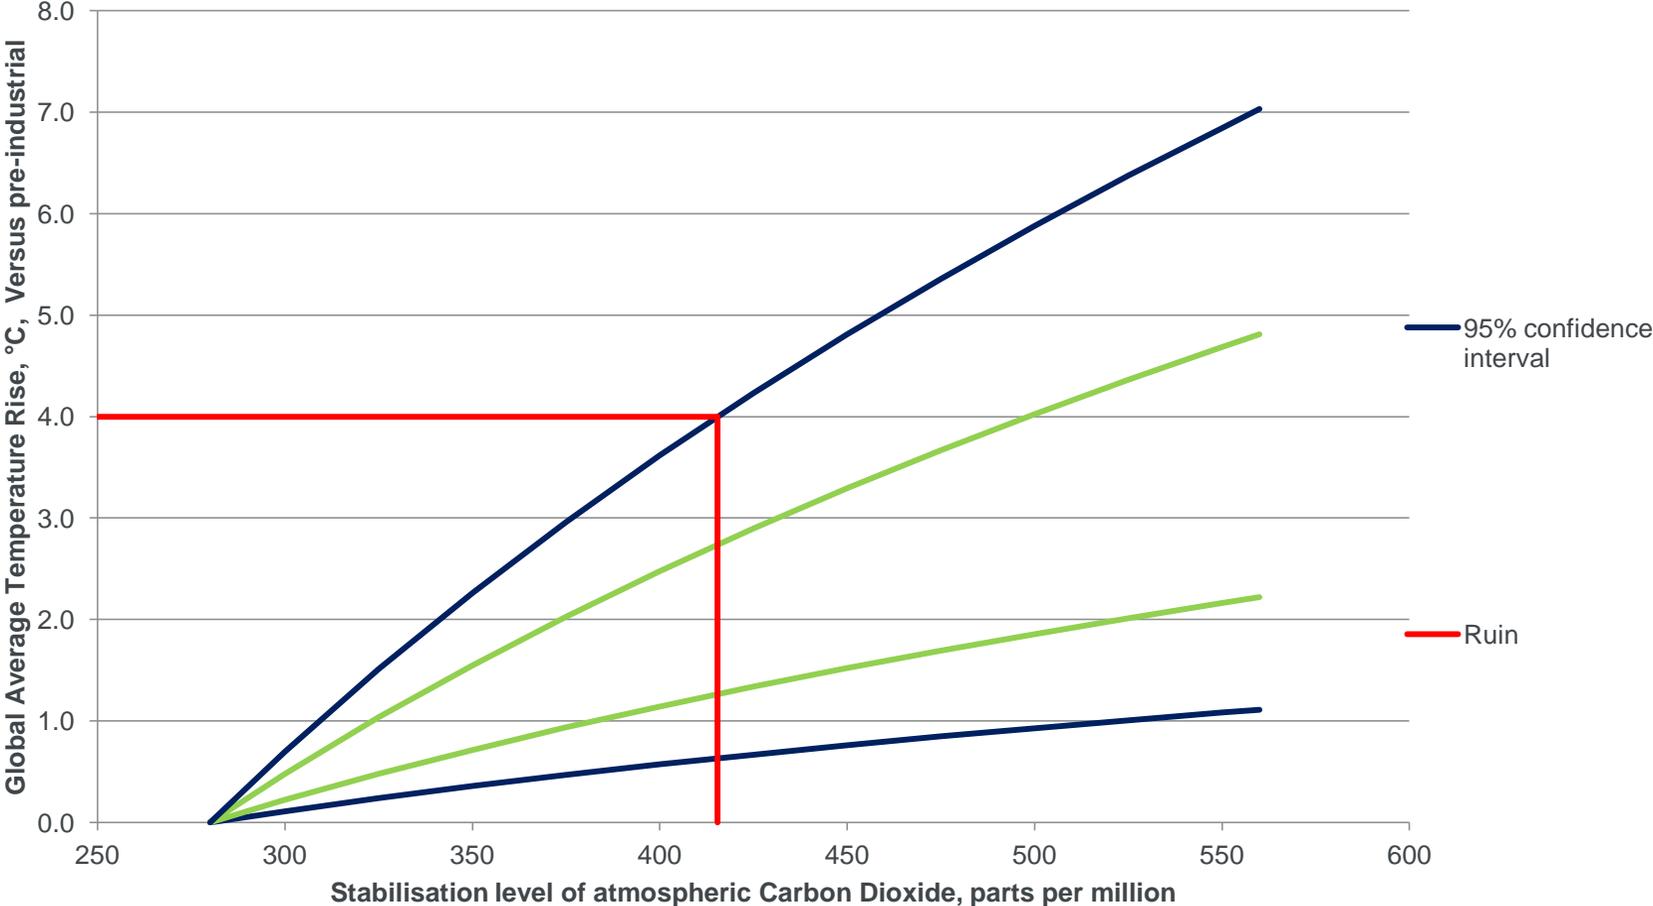

Abstract:

Many palaeoclimate studies have quantified pre-anthropogenic climate change to calculate climate sensitivity (equilibrium temperature change in response to radiative forcing change), but a lack of consistent methodologies produces a wide range of estimates and hinders comparability of results. Here we present a stricter approach, to improve intercomparison of palaeoclimate sensitivity estimates in a manner compatible with equilibrium projections for future climate change. Over the past 65 million years, this reveals a climate sensitivity (in KW^{-1}m^2) of 0.3–1.9 or 0.6–1.3 at 95% or 68% probability, respectively. The latter implies a warming of 2.2–4.8K per doubling of atmospheric CO_2 , which agrees with IPCC estimates.

Plot the 95% Confidence interval for Climate Sensitivity

Read off the carbon dioxide concentration

CO₂ Stabilization Target

Based on these particular inputs and choices, the approximate model results are:

- To limit probability of exceeding 4°C global average temperature rise to $\leq 2.5\%$ *
- Upper bound for the CO₂ stabilization target is $\leq 420\text{ppm}$

* N.B. The 2.5% tail probability risk of ruin has been selected in this model outline only because data is available. The choice of actual acceptable tail probability is a policy decision.

Slow climate feedbacks may lead to higher warming, in the long term

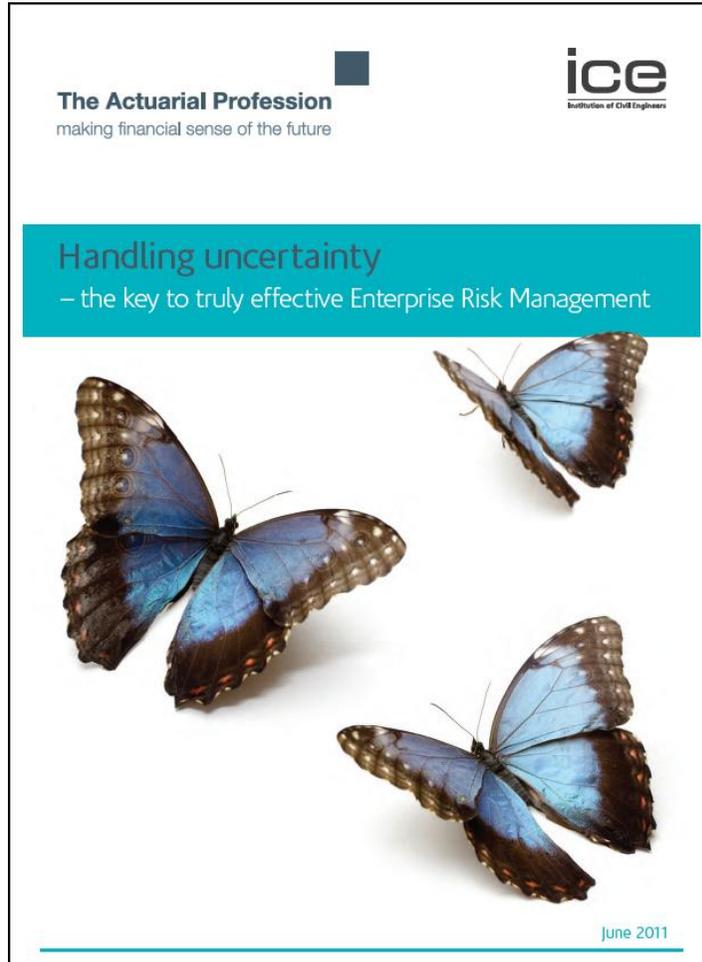

- There is evidence that long term changes e.g. to ice sheets and vegetation, may increase climate sensitivity.
- How can we deal with the risk that slow feedbacks are relevant to us?

Handling uncertainty
– the key to truly effective Enterprise Risk Management

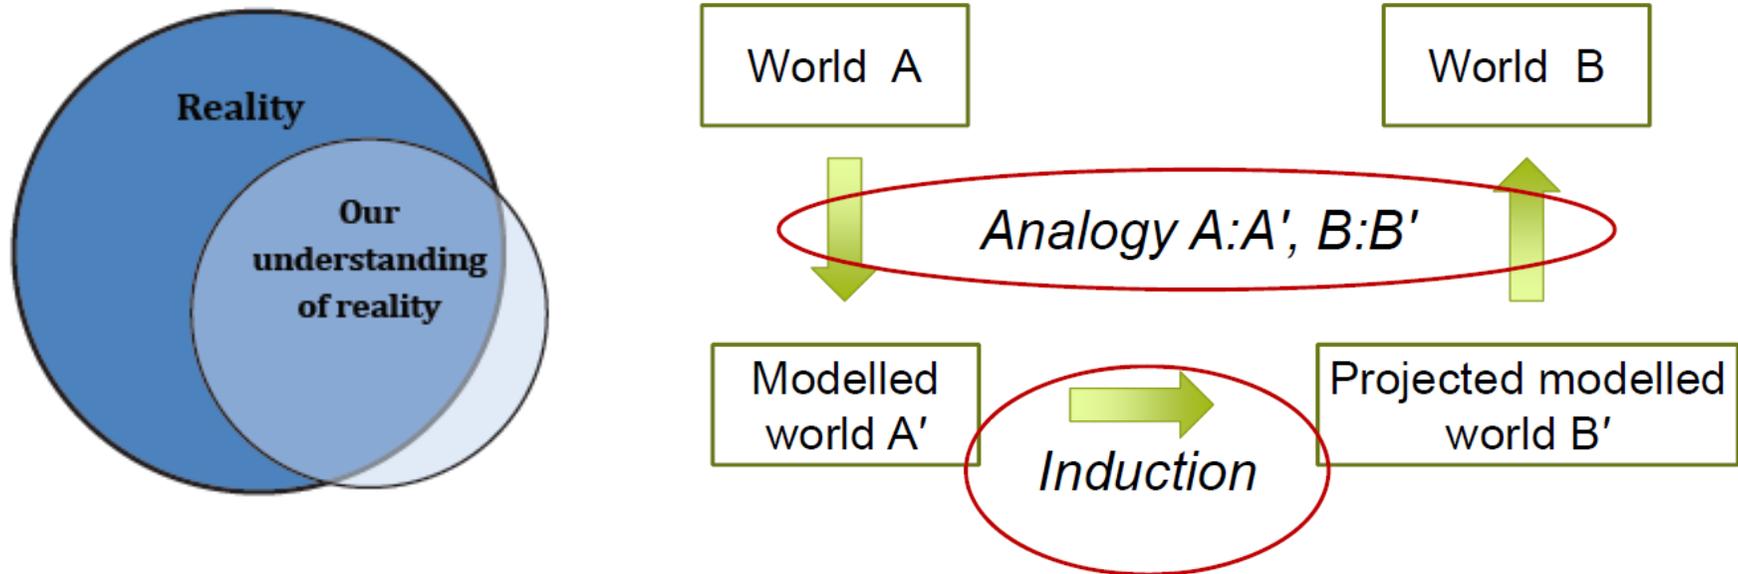

June 2011

- How can we handle uncertainty, i.e. where the probability distribution is not known?
- Prerequisite is an understanding of model output.

Issues of Risk Modelling

Probability range of model output is the range from the model, not the range of outcomes for the modelled system.

Diagrams from 'The Philosophy of Modelling', by Matthew Edwards and Zaid Hoosain, presented to the Staple Inn Actuarial Society, 26 June 2012

http://www.sias.org.uk/diary/view_meeting?id=SIASMeetingJune2012

Areas for Further Investigation

1. Investigation of uncertainty in modelling the climate system. E.g. clouds and long term feedbacks.
2. Discussion around risk tolerance for tail risk.
3. Risk management – what is the contingency plan if actual climate sensitivity is in the tail of the probability distribution?
